1 Prerequisite Mathematics

§1.1 Vectors

Vectors are quantities with magnitude and direction, contrastingly to scalars which only have magnitude. For our purposes, vectors can be understood as directed line segments, although they're more rigorously defined as elements of a vector space, or can be understood through rotations. We'll talk about rotations later, but will not deal with vector spaces right now.

I shall use boldface to denote vectors, such as $\mathbf{A}$.

The utility of vectors stem from their independence from a particular coordinate system. They're directed *line segments*, only their length matters and we're not concerned with their end points. This means that a vector can be freely translated.

Figure 1.1: Identical Vectors

The magnitude of a vector, its norm, is its euclidean "length", we denote it by $\|\mathbf{A}\|$ or simply A.

A unit vector, $\hat{\mathbf{a}}$ ("a hat") is a vector whose magnitude is unity. We use the unit vector to often denote the direction of a vector by multiplying the unit vector with its magnitude. For instance, the unit vector that point is the direction of A, $\hat{\mathbf{A}}$ can be calculated as,

$$\hat{\mathbf{A}} = \frac{\mathbf{A}}{A}$$

where we divide by the magnitude of A to ensure that the magnitude of $\hat{\mathbf{a}}$ is 1.

§1.2 Vector Algebra

There are two operations generally defined on vectors, scalar multiplication and vector addition.

§1.2.1 Scalar Multiplication

Multiplying a vector $\mathbf{A}$ by a scalar c results in another vector, $c\mathbf{A}$ parallel or antiparallel(pointing in the opposite direction) to $\mathbf{A}$ scaled by a factor of $|c|$.

If c is positive, then the resultant vector is simply scaled by it. If we multiply a vector by -1, then the result is the simple reversal in direction of vectors. If c is negative, then the vector is reversed and scaled by $|c|$.

Figure 1.2: Scalar Multiplication

§1.2.2 Vector Addition

We define an operation called addition of vectors which produces another vector. To add two vectors, $\mathbf{A}$ and $\mathbf{B}$, we stick the tail of one vector with the head of another.

We can calculate the magnitude of their resultant vector, $\|\mathbf{A}+\mathbf{B}\|$ by using the cosine rule. In fig. 1.3 θ is the angle between $\mathbf{A}$ and $\mathbf{B}$.

FIGURE 1.3: Vector Addition

$$\begin{aligned}
\|\mathbf{A}+\mathbf{B}\|^2 &= A^2 + B^2 - 2AB\cos(\pi-\theta) \\
\|\mathbf{A}+\mathbf{B}\|^2 &= A^2 + B^2 + 2AB\cos\theta \\
\|\mathbf{A}+\mathbf{B}\| &= \sqrt{A^2 + B^2 + 2AB\cos\theta}
\end{aligned}$$

To subtract two vectors, we simply reverse the vector and then add the resulting vector.

Example 1.1. Consider the infinitesimal change vector, $d\mathbf{A} = \mathbf{A}(t+dt) - \mathbf{A}(t)$.

We have,

$$\begin{aligned}
d\mathbf{A} &= A(t+dt)\hat{\mathbf{A}}(t+dt) - A(t)\hat{\mathbf{A}}(t) \\
d\mathbf{A} &= A(t+dt)\hat{\mathbf{A}}(t+dt) - A(t+dt)\hat{\mathbf{A}}(t) \\
&\quad + A(t+dt)\hat{\mathbf{A}}(t) - A(t)\hat{\mathbf{A}}(t) \\
d\mathbf{A} &= A(t+dt)(\hat{\mathbf{A}}(t+dt) - \hat{\mathbf{A}}(t)) + \hat{\mathbf{A}}(t)(A(t+dt) - A(t)) \\
d\mathbf{A} &= A\,d\hat{\mathbf{A}} + dA\hat{\mathbf{A}}
\end{aligned}$$

The first term represents a change in direction and the second represents a change in magnitude.

The magnitude of the first can be calculated as,

First consider fig. 1.4.

Now, let us first work out a geometric argument for $A\,d\hat{\mathbf{A}}$ which is perpendicular to $\mathbf{A}$. In the limiting case, $A\,d\hat{\mathbf{A}}$, the change in magnitude is negligible, we only observe a change in direction. For now, let us consider $\Delta\mathbf{A}$ perpendicular to $\mathbf{A}$ as an approximation.

This allows us to consider a simple geometric argument which gives $\|\Delta\mathbf{A}\| = 2A\sin(\theta/2)$ where θ is the angle between $\mathbf{A}(t_1)$ and $\mathbf{A}(t_2)$.

Since we're considering values of small θ, we may use the small angle approximation, $\sin(\theta) \approx \theta$. Therefore,

FIGURE 1.4: $\Delta\mathbf{A} \perp \mathbf{A}$

$$\|\boldsymbol{\Delta}\mathbf{A}\| \approx 2A \times \frac{\theta}{2} \tag{1.1}$$

$$\approx A \times \theta \tag{1.2}$$

Which is equivalent to $A\Delta\theta$. In the limit $\Delta\theta \to 0$,

$$dA_\perp = A\,d\theta \tag{1.3}$$

Which finally gives us,

$$\left\|\frac{d\mathbf{A}_\perp}{dt}\right\| = A\frac{d\theta}{dt} \tag{1.4}$$

which is the magnitude of $A\,d\hat{\mathbf{A}}$. Thus,

$$\|d\hat{\mathbf{A}}\| = \frac{d\theta}{dt} \tag{1.5}$$

§1.3 Dot Product

The dot product of two vectors results in a scalar and is defined as,

$$\mathbf{A} \cdot \mathbf{B} = AB\cos\theta$$

where θ is the angle between $\mathbf{A}$ and $\mathbf{B}$.

Note that the quantity $\mathbf{A} \cdot \mathbf{B}$ is just A times the magnitude of the projection of $\mathbf{B}$ on $\mathbf{A}$. Similarly, $\mathbf{B} \cdot \mathbf{A}$ is magnitude of the projection of $\mathbf{A}$ on $\mathbf{B}$ times B.

We may note that,

$$\mathbf{A} \cdot \mathbf{A} = A^2$$

Or,

$$A = \sqrt{\mathbf{A} \cdot \mathbf{A}}$$

It can be easily shown that the scalar product distributes over vector addition. Another thing of importance is the identity(which is also easy to derive),

$$\frac{d\mathbf{A} \cdot \mathbf{B}}{dt} = \frac{d\mathbf{A}}{dt} \cdot \mathbf{B} + \frac{d\mathbf{B}}{dt} \cdot \mathbf{A}$$

§1.4 Cross Product

The cross product is another product operation on vectors, this product produces a vector.

It is defined as,

$$\mathbf{A} \times \mathbf{B} = AB\sin\theta\hat{\mathbf{n}}$$

Where $\hat{\mathbf{n}}$ is the vector perpendicular to the plane containing $\mathbf{A}$ and $\mathbf{B}$. Since there are two directions that $\hat{\mathbf{n}}$ can have, we define the two vectors and their cross product to form a right-hand triple.

Place your fingers in the direction of $\mathbf{A}$ and curl them, along the smaller angle, towards $\mathbf{B}$. Then the direction in which your thumb is pointing is the direction of $\mathbf{A} \times \mathbf{B}$.

§1.5 Vectors in Component form

Although we have worked without co-ordinate systems till now, to actually extract any meaning from vector operations, a coordinate system is necessary though the concept it describes is actually independent of any coordinate system. A spatial, three-dimensional coordinate system essentially establishes three basis vectors.

Basis vectors are vectors that are linearly independent. That is, their linear combination,

$$c_1\mathbf{e}_1 + c_2\mathbf{e}_2 + \cdots + c_n\mathbf{e}_n$$

only has a trivial solution of $c_1 = c_2 = \cdots = c_n = 0$, when equated to the n dimensional null vector, $c_1\mathbf{e}_1 + c_2\mathbf{e}_2 + \cdots + c_n\mathbf{e}_n = \mathbf{0}$.

These vectors being linearly independent imply that they can not be written as linear combination of other vectors. Otherwise, we could have simply written the term $\mathbf{e}_i$ as the linear combination of other vectors whenever we needed to use it.

Although it might not be so obvious, all orthogonal sets of vectors are linearly independent. If we represent these as $\{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n\}$, we can construct a set of basis vectors that are not orthogonal as, $\{\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_{n-1}, \mathbf{e}_1 + \mathbf{e_2} + \cdots + \mathbf{e}_n\}$.

Which means that we don't always need the basis vectors to be orthogonal, but in practice we usually adopt orthogonal basis vectors.

In particular, we'll use the basis vectors which have magnitude of 1, i.e. unit vectors.

In cartesian co-ordinates, we use the unit vectors along the three axes, x, y and z. These are written as $\hat{\mathbf{i}}$, $\hat{\mathbf{j}}$ and $\hat{\mathbf{k}}$ respectively.

But how can we write an arbitrary vector $\mathbf{A}$ in terms of these unit vectors? The answer lies in projecting the vector along the axes. We use the dot product for it.

$$A_x = \mathbf{A} \cdot \hat{\mathbf{i}} = A \cos \alpha \tag{1.6}$$

$$A_x = \mathbf{A} \cdot \hat{\mathbf{j}} = A \cos \beta \tag{1.7}$$

$$A_x = \mathbf{A} \cdot \hat{\mathbf{k}} = A \cos \gamma \tag{1.8}$$

Where α, β, and γ are the angles the vector makes with the x, y and z axes respectively. The cosine of these angles are called directional cosines.

Thus, we write $\mathbf{A}$ in terms of it elements, in matrix form, as,

$$\mathbf{A} = \begin{pmatrix} A_x \\ A_y \\ A_z \end{pmatrix} \tag{1.9}$$

Now scalar multiplication is simply,

$$c\mathbf{A} = \begin{pmatrix} cA_x \\ cA_y \\ cA_z \end{pmatrix}$$

And vector addition is,

$$\mathbf{A} + \mathbf{B} = \begin{pmatrix} A_x + B_x \\ A_y + B_y \\ A_z + B_z \end{pmatrix}$$

For the dot product, representing $\mathbf{A}$ and $\mathbf{B}$ in terms of the basis vectors,

$$\mathbf{A} \cdot \mathbf{B} = (A_x\hat{\mathbf{i}} + A_y\hat{\mathbf{j}} + A_z\hat{\mathbf{k}}) \cdot (B_x\hat{\mathbf{i}} + B_y\hat{\mathbf{j}} + B_z\hat{\mathbf{k}})$$
$$\mathbf{A} \cdot \mathbf{B} = A_xB_x + A_yB_y + A_zB_z$$

Where we use the distributive property of dot product and the fact that $\hat{\mathbf{i}} \cdot \hat{\mathbf{j}} = \hat{\mathbf{j}} \cdot \hat{\mathbf{k}} = \hat{\mathbf{k}} \cdot \hat{\mathbf{i}} = 0$.

We can find the angle between two vectors, θ, as,

Figure 1.5: Two arbitrary vectors

$$\cos\theta = \frac{\mathbf{A}\cdot\mathbf{B}}{AB}$$

Given two vectors $\mathbf{A}$ and $\mathbf{B}$, we can find the projection of one along the *direction* of the other by using the dot product.

We use the fact that the vector $\mathbf{A}$ along $\mathbf{B}$ is simply $\mathbf{A}\cdot\hat{\mathbf{B}}$. Since this is the magnitude, we now simply multiply this by $\hat{\mathbf{B}}$.

The projection of $\mathbf{A}$ along the direction perpendicular to $\mathbf{B}$ is simply $\mathbf{A} - (\mathbf{A}\cdot\hat{\mathbf{B}})\hat{\mathbf{B}}$.

The two directions can be seen in fig. 1.6.

FIGURE 1.6: $\mathbf{A}$ projected along directions tangential and perpendicular to $\mathbf{B}$.

Example 1.2. Consider the unit vectors along the incident, reflected, and normal ray. Given that the unit vectors along the incident ray and normal ray are $\hat{\mathbf{I}}$ and $\hat{\mathbf{N}}$ respectively, find the reflected unit vector.

Solution. The projection of $\hat{\mathbf{I}}$ perpendicular and tangential to the normal are $\hat{\mathbf{I}} - (\hat{\mathbf{I}}\cdot\hat{\mathbf{N}})\hat{\mathbf{N}}$ and $(\hat{\mathbf{I}}\cdot\hat{\mathbf{N}})\hat{\mathbf{N}}$.

Clearly, for the reflected unit vector, the direction of the perpendicular will remain the same while of the tangential will be flipped. Thus, the components of $\hat{\mathbf{R}}$ along the normal are, $\hat{\mathbf{I}} - (\hat{\mathbf{I}}\cdot\hat{\mathbf{N}})\hat{\mathbf{N}}$ and $-(\hat{\mathbf{I}}\cdot\hat{\mathbf{N}})\hat{\mathbf{N}}$. Adding these vectors gives us $\hat{\mathbf{R}}$,

$$\hat{\mathbf{R}} = \hat{\mathbf{I}} - 2(\hat{\mathbf{I}}\cdot\hat{\mathbf{N}})\hat{\mathbf{N}}$$

□

FIGURE 1.7: Incidence, normal and reflected unit vectors.

Finally, the cross product is a little difficult to compute. It can be computed either as the determinant,

$$\mathbf{A}\times\mathbf{B} = \begin{vmatrix} \hat{\mathbf{i}} & \hat{\mathbf{j}} & \hat{\mathbf{k}} \\ A_x & A_y & A_z \\ B_x & B_y & B_z \end{vmatrix}$$

Or using the matrix notation,

$$\begin{pmatrix} A_x \\ A_y \\ A_z \end{pmatrix} \times \begin{pmatrix} B_x \\ B_y \\ B_z \end{pmatrix} = \begin{pmatrix} A_yB_z - A_zB_y \\ A_zB_x - A_xB_z \\ A_xB_y - A_yB_x \end{pmatrix}$$

To compute a particular component, cover up that particular row. Then, multiply the component of $\mathbf{A}$ in the row below (loop to the top if necessary) with the diagonal component of $\mathbf{B}$ and subtract it by the product of the component of $\mathbf{A}$ two rows below, and the diagonal component of $\mathbf{B}$. For example, for the y-component,

$$\begin{pmatrix} A_x \\ - \\ A_z \end{pmatrix} \times \begin{pmatrix} B_x \\ - \\ B_z \end{pmatrix}$$

And the term simply is $A_zB_x - A_xb_z$ by looping through the top.

If $\mathbf{A}\times\mathbf{B} = 0$, then using the component form,

$$A_yB_z - A_zB_y = 0$$
$$A_zB_x - A_xB_z = 0$$
$$A_xB_y - A_yB_x = 0$$

Solving for them leads to,

$$\frac{A_x}{B_x} = \frac{A_y}{B_y} = \frac{A_z}{B_z}$$

§1.6 Some geometric results regarding vectors

§1.6.1 Lami's Theorem

Consider three vectors, $\mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3$ such that $\mathbf{A}_1 + \mathbf{A}_2 + \mathbf{A}_3 = 0$. If the angles θ_1, θ_2 and θ_3 are chosen according to fig. 1.8, then,

Theorem 1.3 (Lami's Theorem).

$$\frac{A_1}{\theta_1} = \frac{A_2}{\theta_2} = \frac{A_3}{\theta_3}$$

FIGURE 1.8: Lami's Theorem

The proof follows from arranging the vectors as sides of a triangle and then applying the sine law. Note that the angles between the sides would be $\pi - \theta_i$. Since $\sin(\pi - \theta) = \sin\theta$, we can simply replace them.

§1.6.2 Internal and External Segments

Consider a point P between the points A and B which divides the line segment $\overline{AB}$ into two parts, $\overline{AP}$ and $\overline{PB}$ where

$$\frac{AP}{PB} = \frac{m}{n}$$

Theorem 1.4. *Given that the position vector of A is $\mathbf{r}_A$ and of B is $\mathbf{r}_B$, the position vector of P will be,*

$$\mathbf{r}_P = \frac{n\mathbf{r_A} + m\mathbf{r_B}}{m+n} \tag{1.10}$$

The proof is almost trivial if you know the section theorem. Then we can just apply the theorem for all components of $\mathbf{r}_{A,B}$ and add them to get the desired result.

The same result if P lies on the extension of $\overline{AB}$ and

$$\frac{AP}{BP} = \frac{m}{n}$$

is,

$$\boxed{\mathbf{r}_P = \frac{n\mathbf{r_A} - m\mathbf{r_B}}{m-n}} \tag{1.11}$$

This can also be derived geometrically by consider two vector triangles.

Another important result, the component wise proof of which we'll take as granted from co-ordinate geometry is of the centroid of a triangle. Given position vectors of the vertices $\mathbf{r}_A$, $\mathbf{r}_B$ and $\mathbf{r}_\mathbf{C}$, the position vector of the centroid of the triangle is,

$$\boxed{\mathbf{r}_C = \frac{\mathbf{r}_A + \mathbf{r}_B + \mathbf{r}_C}{3}} \tag{1.12}$$

FIGURE 1.9: Angle bisector of 2θ.

§1.6.3 Angle Bisectors

Given two vectors $\mathbf{A}$ and $\mathbf{B}$, we can find out the direction of the angle bisector of the angle between them.

A natural instinct might be to construct something like a parallelogram. Well, that doesn't quite work since the resultant does not co-incide with the angle bisector.

But we can use a parallelogram of $\hat{\mathbf{A}}$ and $\hat{\mathbf{B}}$ to construct a rhombus — whose diagonal, the resultant of these vectors lies along the angle bisector! Constructing and shifting parallelly the external angle bisector, we find it lies along the other diagonal, the difference of the two unit vectors.

Note that $\hat{\mathbf{A}} + \hat{\mathbf{B}}$ is not a unit vector, we will need to find the unit vector along that direction.

FIGURE 1.10: The internal angle bisector lies along $\hat{\mathbf{A}} + \hat{\mathbf{B}}$ and the external lies along $\hat{\mathbf{A}} - \hat{\mathbf{B}}$.

§1.6.4 Loci

A set of points that fulfill some particular condition are called a locus. Some loci that will be of our use are given.

Circle

A point lies on a circle with center at (h, k) if it is at some fixed distance, r, the radius from the center. Thus, if the point has co-ordinated x, y it must obey the equation,

$$(x - h)^2 + (y - k)^2 = r^2. \tag{1.13}$$

The area of such a circle is πr^2 and its perimeter is $2\pi r$.

Sphere

A natural extension of the circle into 3 dimensions is the sphere. If the center of the sphere is at h, k, f, then the co-ordinate of any point on its surface will be determined by,

$$(x - h)^2 + (y - k)^2 + (z - f)^2 = r^2 \tag{1.14}$$

For some fixed z, the x and y co-ordinates just form a circle. Thus, a sphere can be thought of being made up these circles. The idea is useful in differential analysis.

Ellipse

A ellipse is a weirder shape. It is a sort of stretched circle, and the stretching is non-uniform across the two dimensions. In fig. 1.11, the length of the semi-minor axis is commonly denoted as b and that of the semi major axis is a. Then any point on the ellipse must have co-ordinates (x, y) such that,

FIGURE 1.11: Ellipse by Ag2gaeh CC BY-SA 4.0, https://commons.wikimedia.org/w/index.php?curid=57497218

$$\frac{(x-h)^2}{a^2} + \frac{(y-k)^2}{b^2} = 1 \tag{1.15}$$

The distance of the foci from the center is its linear eccentricity, $c = \sqrt{a^2 - b^2}$. Overall, the ellipse and other conic sections are characterized by their eccentricity,

$$e = \sqrt{1 - \frac{b^2}{a^2}}$$

The eccentricity of the ellipse ranges from 0 which is just a circle, to 1 where it becomes a parabola. The area of the ellipse is πab. However, its perimeter only has a solution through an infinite series integral, so we'll leave it out for now.

An ellipse can extended to three dimensions to form a shape called ellipsoid. Its locus is given by,

$$\frac{(x-h)^2}{a^2} + \frac{(y-k)^2}{b^2} + \frac{(z-f)^2}{c^2} = 1 \tag{1.16}$$

Its volume is given by $\frac{4}{3}\pi abc$.

§1.7 Radius of Curvature

The radius of curvature is the radius of the circle which best approximates a curve at any given point. The talk of a circle at any given point can be non-rigorously understood as the circle containing the arc from $(x, f(x))$ to $(x + dx, f(x + dx))$.

We can create a formula of the radius of curvature by first noting that the radius at the point, R_c will be,

$$R_c = \frac{d\ell}{d\theta}$$

Where $d\ell = \sqrt{dx^2 + dy^2} = \sqrt{1 + (f'(x))^2}\, dx$ is uniquely described by that point.

Now we just need to figure out $d\theta$. We can do so by first noting that if the curve is the graph of some differentiable function, f, then,

$$\tan\theta = f'(x)$$

We can differentiate this again with respect to x to get,

$$\sec^2\theta \frac{d\theta}{dx} = f''(x)$$

Using the identity $1 + \tan^2\theta = \sec^2\theta$ and $\tan^2\theta = f'(x)$,

$$(1 + (f'(x))^2)\frac{d\theta}{dx} = f''(x)$$

And,

$$d\theta = \frac{f''(x)}{1 + (f'(x)^2)}\, dx$$

Substituting both of these, we get,

$$\boxed{R_c = \frac{[1 + (f'(x))^2]^{3/2}}{f''(x)}} \tag{1.17}$$

Which can also be written as,

$$R_c = \frac{\left[1 + \left(\frac{dy}{dx}\right)^2\right]^{3/2}}{d^2y/\,dx^2}$$

The radius of curvature allows us to say much about $f''(x)$. In (1.17) clearly the numerator is positive. Thus, the sign of the radius of curvature is uniquely determined by $f''(x)$.

What exactly does the negative sign mean? Well it basically tells whether the circle of that radius lies above or below our curve. In fig. 1.12, we can easily find out where $f''(x)$ is negative or positive depending on where the circle lies. The blue circle of infinite radius is at the inflection point, a point where $f''(x)$ is 0.

An inflection point occurs here since $f''(x)$ changes signs from negative to positive and thus, must become 0 at some point.

Given something like a position time graph, we can easily find where the acceleration is positive by just well, drawing out circles. Nice.

FIGURE 1.12: Circles formed by the radius of curvature for several points. The circles formed by positive ones are in red while the ones by the negative ones are in teal. The blue circle has an infinite radius.

Example 1.5. Find the roc of ellipse at its top most and right most points, $(0, b)$ and $(a, 0)$ centered at $(0, 0)$

Solution. We will here figure out the radius at $(0, b)$ and argue by symmetry for $(a, 0)$. In well actuality, the roc at $(a, 0)$ needs use of parametrized forms and so does the general roc equation.

However, for $(0, b)$ we may note that

$$\left.\frac{dy}{dx}\right|_{(0,b)} = 0.$$

And then implicitly derivate the ellipse equation wrt x. We then obtain,

$$\left.\frac{d^2y}{dx^2}\right|_{(0,b)} = -\frac{b}{a^2}$$

By using (1.17) we get,

$$\left.R_c\right|_{(0,b)} = \frac{-a^2}{b} \tag{1.18}$$

By a bit of an ad-hoc symmetric argument, the roc at $(a, 0)$ is b^2/a. □

It's much better evaluated using the parametric equations.

.

2 Unit and Dimensions

Units are dimension are in many ways what give the abstract ideas of physics some ground in the real life. The dimensions of a physical quantity represent what kind of physical quantity is, while the unit is a measure of that physical quantity.

The distinction is appreciable to know, just not always useful.

§2.1 Dimensions

There are seven fundamental quantities which are assigned specific dimensions. It is not necessary to take these as fundamental, in some perfectly fine formulations like the Planck quantities this is not the case. But we'll not be working in these for now.

Quantity	Unit Name	Unit symbol	Dimension
Mass	kilogram	kg	M
Length	meter	m	L
Time	second	s	T
Electric Current	ampere	A	I
Luminous Intensity	candela	cd	J
Temperature	kelvin	K	Θ
Amount of substance	mole	mol	N

Table 2.1: The 7 fundamental quantities.

For any physical quantity A, we use the notation $[A]$ to denote its dimension. For instance,

$$[F] = MLT^{-2}$$

Evaluating the dimensions has a really neat use, it allows us to check our answers, and establish some relations through the use of *dimensional* analysis.

§2.2 Rules regarding dimensions

There are particle constrains that help us utilise dimensions quite a lot. For one, the dimensions on both sides of an equation must be homogenous, i.e the same. It is nonsense to ask if 1 second is equal to 1 kelvin.

Another constraint is that the operations of addition and subtraction can only be performed on quantities of the same dimension, and indeed you cannot add a metre to a kilogram.

Thus, we arrive at a third derived constraint, namely that the functions such as sin, cos, exp, log must all have dimensionless constraints.

This because for instance, let us take the taylor expansion of e^x,

$$e^x = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} + \dots$$

We note that if we x had a dimension, for example $[x] = L$, then we would be adding L to L^2, L^3 and so on. But this is not permitted, we cannot add a metre to a square metre or a square metre to a cubic metre and so on. Thus, we have that their arguments must be dimensionless.

§2.3 Dimensional Analysis

Suppose that we know that the rest energy of a particle depends on it mass and the speed of light. If we were asked to find a relation determining its rest energy we could use the idea of dimensional analysis.

We see that,

$$E \propto m, c$$

We could note that the dimesion on both side of the equation must have the same dimesions. Thus we need to combine them in such a manner that we get the dimensions of energy.

Since $[c] = LT^{-1}$, $[m] = M$ and $[E] = ML^{-2}T^{-2}$, we can form a guess and say that,

$$E = mc^2,$$

since the dimensions are same across both quantities. In fact this the correct formula!

In general, for some quantity A dependent on parameters $Q_1, Q_2, \dots, Q_n$,

$$A = Q_1^{\alpha_1} \cdot Q_2^{\alpha_2} \cdot \dots \cdot Q_n^{\alpha_n}$$

where each of $\alpha_1, \alpha_2, \dots, \alpha_n$ are constants. Then we simply use dimensional analysis to compute the result.

There are catches, however, suppose that we were asked to find the kinetic energy of the particle which depends on its mass and velocity. We might guess by dimensional analysis alone that it is mv^2, which is obviously false. What dimensional analysis gives us is that,

$$E \propto mv^2$$

And we must attach a constant for a definite answer,

$$E = kmv^2$$

The constants comes out to be $1/2$, but we can't determine it with dimensional analysis alone.

Let us take a particular example now, the pendulum: its period depends on L, g, and the amplitude θ_0.

We note that the amplitude and angles in general are dimensionless since they're arguments of the trig functions. If we use dimensional analysis, we run into a bit of a problem.

If we use dimensional analysis, we see that we can use any combination of θ_0, since they're all dimensionless. In particular, we can use any function of θ_0.

If we ignore θ_0 since its dimensionless, we get that

$$T \propto \sqrt{\frac{L}{g}}$$

We hence attach a dimensionless group, a function of θ_0 to get the period of a pendulum as $T = f(\theta_0)\sqrt{L/g}$.

In general this can be done for any dimensionless group, for instance the resistance of conductor depends on its resistivity, the cross-sectional area, and its length. Say we know their dimensions and get that,

$$R = \rho\frac{L}{A}$$

We could have also formulated by dimensional analysis, that $R = \rho/\sqrt{A}$, the dimensions are the same. In fact, we could multiply it by any function of L^2/A since it is dimensionless.

Theorem 2.1 (Buckingham Pi Theorem). *Dimensional analysis can't always pin down the form of the answer. If one has N quantities with D independent dimensions, then one can form $N - D$ independent dimensionless quantities. Dimensional analysis can't say how the answer depends on them.*

This is one of the limitations of dimensional analysis.

§2.4 Limiting Cases

Sometimes we can verify our answers using limiting cases.

Suppose that we don't remember if the acceleration of a block on a smooth, non-accelerating wedge is $g\sin\theta$ or $g\cos\theta$.

We can then consider the limiting cases of θ. For instance, if $\theta \to 0$ then the block rests on a horizontal plane and experiences no acceleration, which is only satisfied by $g\sin\theta$. We could have also looked at $\theta \to \pi/2$ as another limiting case.

PART A

Mechanics

3 Kinematics

Kinematics is the study of motion without concerning its cause. It allows us to calculate and find out the evolution of a body. Everything in our world undergoes motion, one way or the other. To begin our study of motion, let us first concern ourselves with some definitions.

§3.1 Reference Frame and Point Particle

Motion of any object is considered to relative to an observer. The observer defines a particular co-ordinate system called the reference frame

Figure 3.1: A Reference Frame

We use a reference frame according to our convenience. In general, we use the 3-dimensional cartesian system like the one in fig. 3.1.

Definition 3.1 (Reference Frame)

A reference frame is a co-ordinate frame relative to which motion of a particle is considered.

We shall, until we encounter rigid body systems consider the motion of a point particle. Well, why? It is done so to simplify the calculation of our system. The motion of a (rigid)body is discussed later.

Definition 3.2 (Point Particle)

A particle whose size is negligible in the study of its motion is called a point particle.

To discuss the motion, state of our body, it is also necessary to setup some time co-ordinate. It is the reading of the clock in the observer's frame. In general, we setup our clocks at 0 at the start of an event.

§3.2 Position Vector and Displacement

§3.2.1 Position Vector

One thing of importance is that a position vector of a particle is a function of time. We generally denote this as $r(t)$ to show that is a function.

We define the position of a particle relative to a reference frame using a *position vector*. One end of the position vector is the origin of our reference frame. The other is the particle itself. Consider fig. 3.2, the vector $\mathbf{r}$ from O to A. It describes the position of A relative to the co-ordinate frame. Let $A = (x, y, z)$. Then we denoted $\mathbf{r}$ as $\mathbf{r}(x, y, z)$.

The position to any point is written as,

$$\mathbf{r} = (x, y, z) = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$$

FIGURE 3.2: A position vector, $\mathbf{r}$.

§3.2.2 Displacement

Note that the position vector is not a true *vector. It is tied to particular reference frame.*

Consider the movement of a particle from $A = (x_1, y_1, z_1)$ to $B = (x_2, y_2, z_2)$. The *displacement* is the change in the position vector, and defines a true vector $\mathbf{s} = (x_2 - x_1, y_2 - y_1, z_2 - z_1)$. $\mathbf{s}$ is called the displacement vector. Note that it contains no information about the individual positions, but only about the relative position of each. Thus, our choice of reference frame, and thus position vector does not matter when we're concerned with displacement. In fig. 3.3, the vector $\mathbf{S}_{AB}$ defines a displacement from A to B.

FIGURE 3.3: Displacement from A to B

The difference between displacement and distance is that of the path they describe. The distance covered is the length of the actual path, while the magnitude of the displacement is simply the length of the vector between the final and initial positions.

FIGURE 3.4: Distance

Algorithm 3.3 — Consider the case of displacement and distance of a particle in circular motion with radius r Let it move from A to B, inscribing an angle θ (in radians) Then, we have,

Distance between A, $B = r\theta$

Displacement between A, $B = 2r\sin\left(\dfrac{\theta}{2}\right)$

FIGURE 3.5: Displacement in a circle

§3.3 Speed and Velocity

We are already familiar with the notion of speed. In elementary terms, speed is *distance/time*. Speed itself is an elementary concept. It tells us nothing about the direction of the object whose speed we are talking into consideration. Thus, it is a *scalar* quantity.

The symbol $\equiv$ stands for 'defined as'.

The Velocity of a particle, contrastingly, contains information about both the speed and direction of the object in consideration. It is a vector. Similar to position, it is also a function of time $v(t)$, though it may also be dependent

on the position $v(x)$. Even when that is the case, it can still be written as function of time.

Definition 3.4 (Velocity)

Velocity is defined as,

$$\mathbf{v} \equiv \dot{\mathbf{r}} \tag{3.1}$$

In particular, velocity is a function that maps three values — the velocity components of the particle to a particle time instant,

$$\mathbf{v} : \mathbb{R} \to \mathbb{R}^3.$$

This is actually independent of the co-ordinate system we adopt. For any particle, we require merely three co-ordinates to describe its velocity.

The same holds for position as well,

$$\mathbf{x} : \mathbb{R} \to \mathbb{R}^3.$$

Infact to describe the motion of any body, we merely require its initial position and velocity functions. Well, not quite, we also need the equations of motion, of how the system evolves. These end up being second order differential equations in Lagrangian Mechanics with which we'll deal later.

One thing of note is that velocity can also be expressed as the derivative of displacement, which is just $\mathbf{r} - \mathbf{r}_0$. Since the latter term is constant, we simply get that $\dot{\mathbf{s}} = \dot{\mathbf{r}}$.

From this definition, we may gather that,

$$\int_{r_0}^{r} d\mathbf{r} = \int_0^t \mathbf{v}\, dt$$

Or,

$$\mathbf{r} = \mathbf{r}_0 + \int_0^t \mathbf{v}\, dt \tag{3.2}$$

Sometimes, we do not need to compute the derivative of the position vector, and simply need an average estimate, or in the case of uniformly accelerated motion, it is not required that we computer derivatives. In such a case we use the concept of **average velocity**,

$$\overline{\mathbf{v}}_{12} = \frac{\Delta \mathbf{s}}{t_2 - t_1}$$

The dot over r in $\dot{\mathbf{r}}$ tells us that r has been differentiated with respect to time.

Algorithm 3.5 — Let us consider the cases of average velocity,

Case I When there are n equal time intervals with velocity $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$. Then,

$$\overline{\mathbf{v}} = \frac{\mathbf{v}_1 + \mathbf{v}_2 + \cdots + \mathbf{v}_n}{n}$$

Case II When there are n equal intervals of distance/displacement with velocity $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$. Then,

$$\overline{\mathbf{v}} = \frac{n}{\frac{1}{\mathbf{v}_1} + \frac{1}{\mathbf{v}_2} + \cdots + \frac{1}{\mathbf{v}_n}}$$

In general velocity is also referred to as 'instantaneous velocity'. This is done to remind of the difference with average velocity. We will not refer to it that way since by velocity we shall always mean $\mathbf{v}$ as defined in definition 3.4. The same goes for speed. Notably, speed is not defined as $\dot{d}$ where d is the distance.

While the average speed is very well that, speed is actually the magnitude of the velocity of that point. Consider the distance between a and b as $a \to b$. The path between them approaches a straight line. Thus, the distance and displacement become the same in the limiting case. Therefore, the *magnitude* of velocity is the speed at that instant.

Therefore,

$$\text{speed} = \left| \frac{d\mathbf{r}}{dt} \right|$$

Algorithm 3.6 — Let us consider some techniques for solving equations of velocity. Consider the case when velocity and time are given and we have to figure out displacement or when displacement and and velocity are given, but time is not.

1. $v = c$: This is a trivial case. Just use equations of uniformly accelerated motion.
2. $v = f(x)$: $\dfrac{dx}{dt} = f(x)$. Then, $\dfrac{dx}{f(x)} = dt$. Now, we simply have,

$$\int_{x_1}^{x_2} \frac{dx}{f(x)} = \int_{t_1}^{t_2} dt$$

   to get x_1 and x_2 or t_1 and t_2. We may also set our co-ordinates such that $x_2 = x$, $x_1 = 0$ and $t_2 = t$, $t_1 = 0$.
3. $v = f(t)$: This is also easy, just, $f(x) = \dfrac{dx}{dt}$, then,

$$\int_{t_1}^{t_2} f(t)\, dt = \int_{x_1}^{x_2} dx$$

   We simply get x_1 and x_2 or t_1 and t_2 by solving the integral.

§3.4 Acceleration

If a body does not move with uniform velocity, it accelerates. Acceleration is also a vector and is the rate of change of velocity.

Definition 3.7 (Acceleration)

Acceleration is defined as,

$$\mathbf{a} \equiv \dot{\mathbf{v}} = \ddot{\mathbf{r}} \tag{3.3}$$

Much like the velocity definition, we have,

$$\mathbf{v} = \mathbf{v}_0 + \int_0^t \mathbf{a}\, dt \tag{3.4}$$

There is also another way to represent acceleration, as,

$$\mathbf{a} = \mathbf{v}\frac{d\mathbf{v}}{dx}$$

Such a representation is particularly useful when the velocity of a particle is a function of its position. In such a case, derivating with time is quite a hassle.

§3.5 Uniformly Accelerated Motion

When the acceleration of a particle, a is constant, it undergoes uniformly accelerated motion. We use special cases of integrals of a and v with respect to time and position for deriving the equations of importance.

Theorem 3.8. *For a particle with initial velocity u undergoing uniformly accelerated motion of acceleration a,*

$$v = u + at \tag{3.5}$$

$$v^2 = u^2 + 2as \tag{3.6}$$

$$s = ut + \frac{1}{2}at^2 \tag{3.7}$$

$$s_n = u + \frac{a}{2}(2n - 1) \tag{3.8}$$

The derivation of these is quite easy, integrate $\int a\,dx$ for the first, $\int a\,dt$ for the second (both with constant acceleration), substitute from the former into the latter for the third, and finally for n^{th} second just do $s_n - s_{n-1}$.

Some particularly elementary examples demonstrating some tricks are now given.

Example 3.9. Consider a particle moving with acceleration α initially. After some time, it starts to 'de-accelerate' at β acceleration. After time $t = T$, the particle comes to a stop. Find the displacement covered by particle in time T.

Solution. It might be tempting to start calculating after setting up time $t = t_0$ when acceleration changed from α to β, i.e., the particle moves with acceleration α till $t = t_0$.
However, let us try to do a cleaner solution. Consider the $v - t$ graph of the particle,

Note that $\alpha(t_0) = \beta(T - t_0) = v_{max}$. Thus,

$$\begin{aligned}
\alpha(t_0) &= \beta(T - t_0) \\
\alpha(t_0) &= \beta(T) - \beta(t_0) \\
\alpha(t_0) + \beta(t_0) &= \beta(T) \\
t_0 &= \frac{\beta T}{\alpha + \beta} \\
v_{max} &= \alpha t_0 \\
v_{max} &= \frac{\alpha\beta T}{\alpha + \beta}
\end{aligned}$$

Now, note that $\frac{1}{2} \times v_{max} \times T$ is the area under the graph.

The thing to note here is that since the physical quantities are often related in a differential form, they can be converted into an integral form and thus, we can often consider the area under the curve for measures.

Thus, displacement, $s = \frac{\alpha\beta T^2}{2(\alpha + \beta)}$. □

Example 3.10. A car is at distance d from a boy. It starts accelerating at a m/s^2. What is the minimum velocity that the boy should have to catch up with the car.

Solution. Consider separation of boy and car, $s_{c,b}$. Using the equations of motion, we have $s_b = vt$, $s_c = \frac{1}{2}at^2$. Thus,

$$s_{c,b} = d + \frac{1}{2}at^2 - vt \tag{3.9}$$

The most important thing to note here is that,

> **For two objects to meet, the solution for time must be real.**

Therefore, from the simple equation, (3.9), we must have, for real solutions, $b^2 - 4ac$ for the equation $at^2 + bt + c$. Solving for this by substituting values from (3.9), we have,

$$v \geqslant \sqrt{2ad} \tag{3.10}$$

□

Remark 3.11. One thing of note is that the converse of above is true as well,

> **For two objects to *not* meet, the solution of time must be imaginary or negative.**

One more key note to takeaway is that,

At instant of maximum separation, relative velocity of particles is 0.

Example 3.12. A body is dropped at $t = 0$, after time $t = t_0$, another body is thrown downwards with velocity u m/s. Assuming first body reaches ground first, plot graph of separation.

Solution. At instant t_0, displacement of first particle $= \frac{1}{2}gt_0^2$. Note that here we set up co-ordinates such that positive y is downwards from point of drop. The displacement of first body at $t = t$ after t_0 but before $\boxed{\text{reaching ground}}$ is

$$s_1 = \frac{1}{2}gt_0^2 + \frac{1}{2}g(t - t_0)^2 \tag{3.11}$$

While for second body is,

$$s_2 = ut + \frac{1}{2}g(t - t_0)^2 \tag{3.12}$$

Thus,

$$s_{1,2} = \frac{1}{2}g(t_0)^2 + t(gt_0 - u) \tag{3.13}$$

Thus, before reaching ground, $s - t$ graph is linear. However, after first body reaches ground,

$$s_{1,2} = ut + \frac{1}{2}g(t)^2 \tag{3.14}$$

which is a parabola. Thus, overall graph is,

□

Example 3.13. Find the total displacement if the $v - t$ graph is as follows,

The idea behind this is simple, the graph here is **not** a semicircle. It is an ellipse, because of dimensional limitations! The equations of circle, $v^2 + t^2 = r^2$ doesn't work because we cannot add two dimensionally different quantities.

Therefore, the graph is an ellipse, and we conclude by computing the area of the ellipse. I haven't given the data, since I wanted to mention the idea.

§3.6 Motion in Polar Co-ordinates

The polar co-ordinate axes are the two-dimesional subset of the 3-d cylindrical co-ordinates. Any point in polar co-ordinates is depicted by a system of two unit vectors, $\hat{\mathbf{r}}$ and $\hat{\boldsymbol{\theta}}$. However, each of these are $\boxed{\text{dependent on the position of the particle}}$ and maybe written explicitly as $\hat{\mathbf{r}}(\theta)$ and $\hat{\boldsymbol{\theta}}(\theta)$.

Here, $\hat{\mathbf{r}}$ points in the direction of increasing radius(along the radial vector) $\hat{\boldsymbol{\theta}}$ points in the direction of increasing θ (tangent to the radial vector). These two unit vectors are *orthogonal* at any point.

FIGURE 3.6: Unit vectors in polar co-ordinates

In fig. 3.6 if $\mathbf{r}$ makes an angle θ with the horizontal, then,

$$\hat{\mathbf{r}} = \cos\theta\hat{\mathbf{i}} + \sin\theta\hat{\mathbf{j}} \tag{3.15}$$

$$\hat{\boldsymbol{\theta}} = -\sin\theta\hat{\mathbf{i}} + \cos\theta\hat{\mathbf{j}} \tag{3.16}$$

§3.7 Kinematics in Polar Co-ordinates

Now let us formulate kinematics in polar co-ordinates. The position $\mathbf{r}$ can be written as

$$\mathbf{r} = r\hat{\mathbf{r}} \tag{3.17}$$

Velocity follows normally,

$$\mathbf{v} = \dot{\mathbf{r}} = \dot{r}\hat{\mathbf{r}} + r\frac{d\hat{\mathbf{r}}}{dt} \tag{3.18}$$

or does it? What even is $\frac{d\hat{\mathbf{r}}}{dt}$? Well the answer lies in the time-derivative of the unit vectors. Using the definitions in (3.15), we get,

$$\frac{d\hat{\mathbf{r}}}{dt} = \dot{\theta}\hat{\boldsymbol{\theta}} \tag{3.19}$$

$$\frac{d\hat{\boldsymbol{\theta}}}{dt} = -\dot{\theta}\hat{\mathbf{r}} \tag{3.20}$$

Using these results, we get that

$$\boxed{\begin{aligned} \mathbf{v} &= \dot{r}\hat{\mathbf{r}} + r\dot{\theta}\hat{\boldsymbol{\theta}} \qquad (3.21) \\ \mathbf{a} &= (\ddot{r} - r\dot{\theta}^2)\hat{\mathbf{r}} + (r\ddot{\theta} + 2\dot{r}\dot{\theta})\hat{\boldsymbol{\theta}} \qquad (3.22) \end{aligned}}$$

The most interesting result are the various terms of acceleration in (3.22). First let us consider the terms along $\hat{\mathbf{r}}$. $\ddot{r}$ is the *radial* acceleration. It is the change is radial speed. The second term $-r\dot{\theta}^2$ is the *centripetal* acceleration. It arises from a change in tangential velocity.

Now let us consider the terms along $\hat{\boldsymbol{\theta}}$. The $r\ddot{\theta}$ term is the tangential acceleration resulting from change in tangential speed. The other term $2\dot{r}\dot{\theta}$ is the *coriolis* acceleration. I shall discuss it when discussing rotating frames.

§3.8 Free Fall

When an object is dropped downwards freely, it undergoes *free fall*. We ignore air resistance, until we're told not to and in general also talk about cases of the object being thrown instead of dropped. An object dropped from any height undergoes accelerations $\mathbf{a}$ where $\|\mathbf{a}\| = g$. The direction and sign of acceleration is entirely dependent on us.

In general, it is a good idea to setup our axes such that the direction above ground is positive and towards the ground is negative. The acceleration during free fall is always towards the ground. Therefore, for these cases $\mathbf{a} = -g\hat{\mathbf{j}}$.

Some important points of note are that "g" does not become positive or negative or whatever, this is a common misconception. Instead, we just decide where exactly the positive direction is and setup g according to that. When a ball is thrown with some velocity u say in the positive directions (change it into $-u$ if in the negative direction), then we have,

Algorithm 3.14 — The following are special cases of equations of motion.

1. $v = u - gt$
2. $v^2 = u^2 - 2gh$

3. $h = ut - \frac{1}{2}gt^2$

The case when a ball is thrown upwards is exactly symmetrical to this one, but there the ball goes up, reachs $v = 0$ and then goes down. Also note that all of these equations are vector equations.

Example 3.15. Two balls are thrown in intervals of 2 seconds with velocity u each. Find the time when they collide.

Solution. Note that when they collide, their displacement from ground must be the same! Setting the origin at ground, and direction of away from ground as positive, we have,

For the first ball, $h_1 = ut - \frac{1}{2}gt^2$. Since the second ball is thrown 2 seconds later, $h_2 = u(t-2) - \frac{1}{2}g(t-2)^2$. Now, we just have $h_1 = h_2$ and the calculation is trivial. □

The thing to note in this example is that you do not need to setup two cases, one in which g is negative and one in which g is positive since it is in the direction of velocity. Just note that these equations are vectorial and we are done.

Some quick formulas to remember because they help a lot,

Algorithm 3.16 — For an object dropped from height h,

1. Time to reach ground, $t = \sqrt{\frac{2h}{g}}$.
2. Velocity when it reaches ground $v = \sqrt{2gh}$.

Deriving them is easy, and they can be generalised as when it travels height h between the point of drop to anywhere, instead of ground. Clearly, both still follow there.

Also, always remember,

When an object is thrown/dropped from another object traveling with some velocity and acceleration, it inherits its velocity but not its acceleration.

§3.9 Graphs in Motion

In the graphs we are going to discuss, acceleration will either be 0 or constant. These graphs help to quickly solve problems, especially related to total distance and displacement.

Let us consider the direction away from origin positive, and towards origin negative. Then, consider constant acceleration, $a = c$. We have the following displacement time graphs,

(a) For $c > 0$. (b) For $c < 0$

I use these in particular to demonstrate concavity and convexity. For a twice differentiable function f, it is concave if $f''(x) > 0$ and convex otherwise.

Displacement Time

Displacement time graphs can be generally interpreted also as position time graphs since the two differ only by a constant initial value.

Their area under the curve, $\int x\,dt$ is not of much use but their slope, $\dot{x}$ represents the velocity. We can also analyze the graphs to figure out whether their roc circle lies above or below the graph to figure out the sign of acceleration at any given moment.

Velocity Time

Their slope is simply $\dot{v}$ or the acceleration. Their area is $\int v\,dt$ which is the displacement. We need to remember that we need to setup definite integrals since these actually give the value we need and not a family of solutions.

Acceleration Time

Acceleration time graphs are useful for their area which represents the difference in velocities in an interval,

$$\int_0^t a\,dt = v(t) - v_0$$

Velocity Displacement

These are the more esoteric and interesting graphs. The slope is simply,

$$\frac{dv}{dx} = \frac{a}{v}$$

where we use the fact that $a = v\,dv/\,dx$. Thus given a velocity time graph we can figure out the acceleration at any given x as,

$$a = v_{x_0} \left.\frac{dv}{dx}\right|_{x_0} = v_{x_0} \tan\theta$$

Example 3.17. Given the velocity time graph in fig. 3.7, sketch out the acceleration time graph.

Solution. We see that $v = mx + c$ where $m < 0$. Now,

FIGURE 3.7: A linear velocity time graph.

$$a = v\frac{dv}{dx} = m(mx + c) = m^2x + mc$$

Thus, it is of form $ax + b$ where $a > 0$, $b < 0$.

There-fore its graph is,

FIGURE 3.8: The corresponding acceleration time graph.

□

Velocity squared time

This is the last family of graphs we'll look at. The integral is largely useless but we note that

$$\frac{dv^2}{dx} = 2v\frac{dv}{dx} = 2a$$

Thus, its slope, $\tan\theta = 2a$ and we can easily figure out its acceleration if we figure out its slope. yay.

§3.10 Relative Motion

There is a very neat technique to solve questions of kinematics, it is to switch our reference frames. Let the base reference frame be that of earth, then,

If $\mathbf{r}_1$ evolves with time, $r_1(t)$. And so does $r_2(t)$. Then,

$$\begin{aligned}\mathbf{r}_1 &= \mathbf{r}_{1,2} + \mathbf{r}_2\\ \dot{\mathbf{r}}_1 &= \dot{\mathbf{r}}_{1,2} + \dot{\mathbf{r}}_2\\ \mathbf{v}_1 &= \mathbf{v}_{1,2} + \mathbf{v}_2\\ \mathbf{v}_{1,2} &= \mathbf{v}_1 - \mathbf{v}_2\end{aligned}$$

Obviously if the vectors face the same direction in the same plane, then, the components subtract. If they face opposite direction, then the components add.

$\mathbf{v}_{1,2}$ is called the velocity of *1* w.r.t *2*. When doing problems, try to setup a reference frame such that velocity of any single object vanishes. This allows for a very neat simplification of problems.

§3.11 Motion in higher dimensions

We can mostly safely extend our results from one dimension to higher dimensions. So for instances, velocity of a particle whose trajectory is defined as $x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$ can simply be computed as,

$$v = \dot{x}\hat{\mathbf{i}} + \dot{y}\hat{\mathbf{j}} + \dot{z}\hat{\mathbf{k}}$$

Such a thing is not true for non-cartesian co-ordinates, as we say in the case of polar forms. Due to the orthogonality of the cartesian unit vectors, and using dot products we simply have,

$$v_x = \dot{x}, v_y = \dot{y}, v_z = \dot{z}$$

And the same is true for all other vectors. This gives us the power to resolve our vector components into components alongside unit vectors and consider independent one dimensional motion for each of them.

§3.12 Projectile Motion

Projectile motion is one of the most important motion to consider in 2 dimensions. It is the motion of a projected body. Generally, we only care about the motion of a body projected from ground under the influence of gravity.

Let a body be projected at an angle θ from the ground at velocity $\mathbf{v}$ along θ. Then, by resolving $\mathbf{v}$ into $v_x\hat{\mathbf{i}} + v_y\hat{\mathbf{j}}$, we have,

$$\begin{aligned}x &= v_x t\hat{\mathbf{i}}\\ y &= v_y t - \frac{1}{2}gt^2\hat{\mathbf{j}}\end{aligned}$$

Doing some manipulations, we may note that $v_x = v\sin(\theta)$, $v_y = v\cos(\theta)$. Also, substituting $t = x/v\sin(\theta)$, we have,

$$\boxed{y = x\tan(\theta) - \frac{gx^2}{2v^2\cos^2(\theta)}} \tag{3.23}$$

We can also use the identity $1/\cos^2\theta = \tan^2\theta + 1$ and get another and perhaps nicer form of the equations,

$$\boxed{y = x\tan\theta\left(1 - \frac{x}{R}\right)} \tag{3.24}$$

after substituting with R[1].

1. *calculated just a bit later.*

The path of the projectile is parabolic as shown in fig. 3.9.

FIGURE 3.9: Trajectory of a projectile

Here, H is the maximum height of the particle. Clearly, when the projectile is at H, $v_y = 0$. We have, $v_y^2 = 2gH$,

$$\boxed{H = \frac{u^2 \sin^2(\theta)}{2g}} \tag{3.25}$$

The time period of the projectile can be simply calculated as well, since at the final time, T, $y = v_y t - 1/2gt^2 = 0$ and,

$$\boxed{T = \frac{2v \sin(\theta)}{g}} \tag{3.26}$$

R is the range the particle covers horizontally in time T and is clearly,

$$\boxed{R = \frac{v^2 \sin(2\theta)}{g}} \tag{3.27}$$

Note that if the particle is projected at $\theta = \pi/4$, the range is maximum and is $u^2/2g$. Otherwise, for $0 < \theta < \pi/2$, $\sin(2\theta)$ attains the same value for two θ_1, θ_2. These θ_1, θ_2 are complementary by trigonometry.

More generally, if we consider the projectile to have an initial position of (x_0, y_0), then, by substituting for time, we find that the vertex of the parabola is $\left(y_0 + \frac{u^2 \sin^2 \theta}{2g}, x_0 + \frac{u^2 \sin 2\theta}{g}\right)$.

The range is a little more difficult to computer here, as the particle will transverse to the ground which is lower than y_0. Freely setting up our co-ordinates as $(h, 0)$, we get by the equation of trajectory,

$$0 = h + R\tan(\theta) - \frac{gx^2}{2v^2 \cos^2(\theta)}$$

Derivating this with respect to theta to find the maxima, and then using the attained value, we have,

$$R = \frac{u}{g}\sqrt{u^2 + 2gh} \tag{3.28}$$

Example 3.18. A projectile starting from one vertex of a wedge, grazes the other vertex and ends upon the other vertex, with an initial velocity v_0 making an angle θ with the horizontal. If the angles of the vertices are α and β, figure out a relation between $\tan\theta$, $\tan\alpha$ and $\tan\beta$.

Solution. Divide the range of the projectile into two lengths, x and x' such that $x + x' = R$. Now, clearly,

$$\tan\alpha = \frac{y_0}{x} \qquad \tan\beta = \frac{y_0}{x'}$$

Also, by the alternate equation of trajectory,

$$y_0 = x\tan\theta\left(1 - \frac{x}{R}\right) = x\tan\theta\left(1 - \frac{x}{x+x'}\right)$$

Which gives us,

$$\tan\theta = y_0\left(\frac{x+x'}{xx'}\right) = \frac{y_0}{x} + \frac{y_0}{x'}$$

Finally substituting the values, we get,

$$\tan\theta = \tan\alpha + \tan\beta \tag{3.29}$$

Pretty nice and useful result.

□

FIGURE 3.10: Projectile grazing a wedge.

Some peculiar things about projectile motion is that, a) it is reversible, and b) the time to attain some vertical displacement can be found in terms of the maximum height alone.

Consider the vertical position of the particle to be s at some time t. Then,

$$s = u_y t - \frac{1}{2}gt^2$$

Also, note that if the maximum height is h,

$$u_y = \pm\sqrt{2gh}$$

Where the positive value is during the ascent and the negative is during the descent. Then,

$$s = \pm\sqrt{2gh}t - \frac{1}{2}gt^2$$

Solving for t gives us,

$$t = \pm\sqrt{\frac{2h}{g}} \pm \sqrt{\frac{2(h-s)}{g}}$$

If the initial velocity is positive and $s > 0$,

$$t = \sqrt{\frac{2h}{g}} \pm \sqrt{\frac{2(h-s)}{g}} \tag{3.30}$$

the two values correspond to the fact that the particle will have the same vertical displacement at two instances of time.

If the initial velocity is positive but $s < 0$, i.e the particle starts at some height but then transverses below it,

$$t = \sqrt{\frac{2h}{g}} + \sqrt{\frac{2(h-s)}{g}} \tag{3.31}$$

is the only reasonable solution.

If the initial velocity is negative, then clearly the particle will attain a lower position. The maximum height in this case is simply the initial height of the particle.

$$t = -\sqrt{\frac{2h}{g}} + \sqrt{\frac{2(h-s)}{g}} \tag{3.32}$$

Somewhat qualitatively, projectile motion is independent of its horizontal range. If some projectiles have same maximum height, their time of flight *will be the same.*

§3.13 Drag Forces

In a more realistic scenario, a particle undergoing motion in any media experiences a drag force, anti-parallel to its velocity. In particular,

$$\mathbf{a} = -\alpha v\hat{\mathbf{v}} - \beta v^2\hat{\mathbf{v}}$$

where the linear term arises from a property of the media, the viscosity(we will talk about it in the later sections.)

The quadratic term is a result of the collision of the particles with atoms and molecules during its motion. In general, the quadratic term dominates for higher velocities.

It is very difficult to analyse motion with drag, but we shall have a look at some particular cases of linear drag.

§4.2.2 Newton's Second Law

Example 3.19. Consider a projectile of mass m thrown upwards with initial velocity v_0. It undergoes a linear drag force, $\mathbf{F} = -kv\hat{\mathbf{v}}$. Find the velocity of the particle as a function of time.

Solution. Using newton's second law, also by noting that it also undergoes gravitation, $\mathbf{a} = -g - kv/m\hat{\mathbf{v}}$.

Now, we note that,

$$\frac{dv}{dt} = -g - \frac{kv}{m}$$

$$\frac{dv}{g + kv/m} = -\,dt$$
$$\int_{v_0}^{v_f} \frac{dv}{g + kv/m} = \int_0^t dt$$
$$\frac{m}{k}\log(g + kv/m)\Big|_{v_0}^{v_f} = t$$

Which finally gives us,

$$v(t) = e^{-kt/m}v_0 + \frac{gm}{k}(e^{-kt/m} - 1) \tag{3.33}$$

□

The same idea can be extended to projectile — 2d motion by considering the components of the accelerations,

$$\mathbf{a} = -kv_x\hat{\mathbf{i}} - (g + kv_y)\hat{\mathbf{j}},$$

and now considering the equations $\dot{\mathbf{v}} = -kv_x$ and the same for the y coordinate.

Ulitmately, this leads to the equations,

$$v_x = u_x e^{-kt} \tag{3.34}$$
$$v_y = \left(u_y + \frac{g}{k}\right)e^{-kt} - \frac{g}{k} \tag{3.35}$$

4 Netwon's Laws

In this chapter we shall look at newton's laws of motion. These form the basis of dynamics which is the study of a motion's cause. In general, we solve mechanical problems by first considering its dynamics and then reduce it to a purely kinematical problem.

First let us concern ourselves with the concept of linear momentum.

§4.1 Linear Momentum

Definition 4.1

The Linear Momentum, $\mathbf{p}$ of a particle of mass m moving with velocity $\mathbf{v}$ is defined as,

$$\mathbf{p} = m\mathbf{v}$$

The total momentum of a system of particles is simply the sum of momentum of each particle. Momentum is a useful quantity because it is conserved, we'll look at that latter. But for now, it has certain unique properties that make the concept of momentum extremely important.

§4.2 Newton's Three Laws

§4.2.1 Newton's First law

Axiom 1. Objects tend to continue in a state of constant velocity unless acted upon by a net external force.

The first law actually is much better stated as the assertion that inertial frames exist.

It defines inertial frames as such reference frames where objects move at constant velocity without the action of an external force. It also makes an empirical observation that such frames exist. Thus, its part definition and part experimental fact.

In fact an inertial frame may also be stated as a frame which has no acceleration. Here, the fact that we can say that it has no acceleration refers to the newtonian concept that acceleration is absolute. That in any frame of reference, we may know that a body is accelerating, even when velocity is relative and an object may be at rest in certain frames and moving in others.

We may measure the acceleration in any reference frame by placing an accelerometer and the acceleration must come out the same no matter what frame we choose.

Since the inertial frames are non-accelerating, they travel with some constant velocity relative to each other. Thus, a frame that travels with constant velocity to an inertial frame is also a reference frame.

Another way to talk about inertial frames is that they are the frames in which newton's laws hold. Certainly, if our frame is non-inertial, none of the laws will hold in this frame.

§4.2.2 Newton's Second Law

A very nice reference which discusses interaction in detail is [KK14]

Axiom 2. The net external force on a body is proportional to its change in momentum.

Thus, our claim is that

$$\sum \mathbf{F} = \frac{d(m\mathbf{v})}{dt} = m\mathbf{a},$$

if the mass is constant.

Let us take an interlude here and talk about what mass and force really are.

Mass

Assume that there are two bodies, of masses m_1 and m_2. If they say, undergo an "equal amount" of physical interaction, for instance two blocks are accelerated with the same amount of "push", and are accelerated with accelerations a_1 and a_2, then,

$$m_2 \equiv m_1 \frac{a_1}{a_2}.$$

We define the mass of the first body relative to the other. The accelerations can be absolutely measured using an accelerometer. In such a manner we define the acceleration of any ith body relative to the first one as,

$$m_i \equiv m_1 \frac{a_1}{a_i}$$

We define some standard mass as 1 unit and then define the other masses relative to this. Such a definition is an operational definition.

It is not always useful, and is not theoretical but it does give us a way to measure the mass of any body.

The talk about equal physical interaction is vague and purely experimental concept. It is entirely physical and has no theoretical basis on which we can rely. It may seem a little wooly, but it works.

Force

We say a force is produced by a physical interaction. We dont talk about what forces "are". Merely, how they come to be. Whenever we interact physically with an object, we apply a force on it.

It might be tempting to ask in case of forces where such an interaction is not visible, say gravity, does this really hold? In fact, it does the interaction is mediated through the use of fields. We'll have a look at them later.

§4.2.3 Newton's Third Law

The final law describes how forces come in pairs and result of a physical interaction.

Axiom 3. If a body A applies a force on a body B, then the body B applies an equal and opposite force on A. These forces are called action-reaction pairs.

That is to say,

$$\mathbf{F}_{AB} = -\mathbf{F}_{BA}.$$

The third law is also known as the weak law of action and reaction — in direct contrast with the strong law which requires the equal and opposite forces to lie on the same line of action. Most forces such as gravity and the normal force in fact obey the strong law of action and reaction.

§4.3 Force on a system of particles

Consider a system of N particles. For an ith particle, by the second law,

$$\left(\sum \mathbf{F}\right)_i + \sum_{j, j\neq i} \mathbf{f}_{ij} = \dot{\mathbf{p}}_i$$

where $\mathbf{F}$ is the external force and $\mathbf{f}_{ij}$ is the internal force on i due to j. Summing this for all N particles,

$$\sum \left(\sum \mathbf{F}\right)_i + \sum_i \sum_{j, j\neq i} \mathbf{f}_{ij} = \sum_i \dot{\mathbf{p}}_i$$

Note that the first term is simply the net external force, $\sum \mathbf{F}_{ext}$. The second term actually goes to zero since if we split the sum into action-reaction pairs, $\mathbf{f}_{ij} + \mathbf{f}_{ji}$, they cancel out by the third law.

So we simply have,

$$\sum \mathbf{F}_{ext} = \sum_{i=1}^{N} \dot{\mathbf{p}}_i$$

It's very difficult to compute the sum of momentums for large values of N. Thus we define something called the *centre of mass*.

Definition 4.2

The position vector, $\mathbf{R}$, of the Centre of Mass of a (system)body of N particles is,

$$\mathbf{R} = \frac{\sum_{i=1}^{N} m_i \mathbf{r}_i}{\sum_{i=1}^{N} m_i} \tag{4.1}$$

If the body has a mass M,

$$M = \sum_{i=1}^{N} m_i,$$

Then, for infintisemal $d\mathbf{r}$,

$$M\,d\mathbf{R} = \sum_{i=1}^{N} m_i\,d\mathbf{r_i}$$

Note that,

$$\sum_{i=1}^{N} \mathbf{p}_i = \sum_{i=1}^{N} m_i \frac{d\mathbf{r}_i}{dt}$$

Thus,

$$\boxed{\sum_{i=1}^{N} \mathbf{p}_i = M\dot{\mathbf{R}}} \tag{4.2}$$

Where let $\mathbf{R}$ is the position vector of the centre of mass(CM). Thus,

$$\sum_{i=1}^{N} \mathbf{p}_i = M\mathbf{v}_{CM}$$

And,

$$\sum_{i=1}^{N} \dot{\mathbf{p}}_i = M\mathbf{a}_{CM}$$

Which finally gives us,

$$\boxed{\sum \mathbf{F}_{ext} = M\mathbf{a}_{CM}.} \tag{4.3}$$

This means that a system of particles evolves translationally due to a net external force as if it were a point particle of mass M located at the center of mass of the system, with a position vector $\mathbf{R}$.

This means that we can simply analyze the translational motion of the center of mass which defines the translational motion of the entire rigid body, as the position vector of the particles are fixed relative to each other.

For continous mass distributions,

$$\mathbf{R} = \frac{\int \mathbf{r}\,dm}{\int dm} \tag{4.4}$$

§4.3.1 Calculating the Centre of Mass

A good reference here is [WR18].

Let us first calculate the centre of mass of two particles of masses m and M located at (x_1, y_1, z_1) and (x_2, y_2, z_2). By definition 4.2,

$$\mathbf{R} = \frac{1}{m+M}\left[\begin{pmatrix} mx_1 \\ my_1 \\ mz_1 \end{pmatrix} + \begin{pmatrix} Mx_2 \\ My_2 \\ Mz_2 \end{pmatrix}\right] = \frac{1}{m+M}\begin{pmatrix} mx_1 + Mx_2 \\ my_1 + My_2 \\ mz_1 + Mz_2 \end{pmatrix}$$

One special thing we may note is that instead of calculating the centre of mass for each particle, we reduce some say n particles or distributions into point particles by first calculating their centre of mass. For instance, instead of calculating the com of three them at once, we can calculate the com of the first two, and then that of the third.

This works because suppose the com of any n particles or distributions is located at $\mathbf{R}$. Then, if we calculate the com of this with another say $n+1$th particle,

$$\mathbf{R}' = \frac{M\mathbf{R} + m_{n+1}\mathbf{r}_{n+1}}{M + m_{n+1}},$$

where M is the total mass of the n particles. By the definition of com,

$$M\mathbf{R} = \sum_{i=1}^{N} m_i \mathbf{r}_i$$

Replacing this,

$$\mathbf{R}' = \frac{\sum_{i=1}^{N} m_i \mathbf{r}_i + m_{n+1}\mathbf{r}_{n+1}}{\sum_{i=1}^{N} m_i + m_{n+1}},$$

Which is simply the com of the $n+1$ particles, at once calculated!

$$\mathbf{R}' = \frac{\sum_{i=1}^{N+1} m_i \mathbf{r}_i}{\sum_{i=1}^{N+1}}$$

The same can be extended to mass distributions.

For example, to calculate the com of two spheres of uniform mass distribution, we may calculate their com, which is at their centre (by a symmetry argument), and then just use our previous result of com of two point masses.

This can also be used to find the com for "missing masses". Where we replace our incomplete system with a complete system having the total mass of the system if it were complete, and a negative mass. This might be a little difficult to understand, so let us look at an example:

FIGURE 4.1: Missing mass

Example 4.3. A uniform circle of radius R has a circular hole of radius $R/2$. The surface density of the circle is σ. Find the centre of mass of the system.

Solution. To calculate the com, we first "fill up" or replace the incomplete the circle with a complete circle. This can then be reduced to a point mass of mass $M = \sigma\pi r^2$.

To counter effect this addition of mass by filling up the circle, we associate a negative mass with the smaller circle, $-m = -\frac{\sigma\pi r^2}{4}$.

Let the origin the com of the first circle, then the first circle, which we have reduced to be a particle at its com, has a position vector, $\mathbf{0}$. Thus, com of the system is,

$$\mathbf{R} = \frac{M \times 0 - mR/2}{M - m} = \frac{-mR/2}{M - m} = \frac{R}{6}$$

□

For continuous distributions, we may use integration to calculate the centre of mass,

Example 4.4. Determine the center of mass of a right-angled triangle of a uni- form surface mass density σ and with an angle of inclination in the xy plane. Let the length of its base be ℓ.

Solution. Note that $\sigma = dm/\,dA \iff dm = \sigma\,dA = \sigma\,dx\,dy$.

So, we can setup a double integral,

$$\mathbf{R} = \frac{1}{M}\int_0^{\ell}\int_0^{x\tan\theta} x\hat{\mathbf{i}} + y\hat{\mathbf{j}}\sigma\,dy\,dx$$

Splitting up the integrals,

$$\begin{aligned}
R_x &= \frac{1}{M}\int_0^{\ell}\int_0^{x\tan\theta} x\sigma\,dy\,dx \\
R_x &= \frac{1}{M}\int_0^{\ell} \sigma\,xy\Big|_0^{x\tan\theta} dx \\
R_x &= \frac{1}{M}\int_0^{\ell} x^2\tan\theta\sigma\,dx \\
R_x &= \frac{1}{M}\,\frac{x^3\sigma\tan\theta}{3}\Big|_0^{\ell} \\
R_x &= \frac{2}{\ell^2\sigma\tan\theta}\,\frac{\ell^3\sigma\tan\theta}{3} \\
R_x &= \frac{2\ell}{3}
\end{aligned}$$

And by a similar procedure, $R_y = \ell\tan\theta/3$. Which gives you $\mathbf{R}$.

□

§4.4 Some Phenomenological Forces

§4.4.1 The Normal Force

The contact force on a body can be resolved to two mutually perpendicular forces, the normal force, perpendicular to the object, and friction, tangential to the object.

These contact forces arise due to atomic interactions. If we say keep a book on a table, the book pushes against the table. On a microscopic scale, the molecules push against each other. After a certain point, the molecules start repulsing each other and the table applies a normal force, perpendicular to the body, to stop it.

Since no object is perfectly rigid, there always occurs a deformation on its surface. However, this is usually negligible, and we may safely assume that the object is perfectly rigid.

§4.4.2 Friction

Friction much like the normal force, arises from molecular interactions. It is, however, way too complex to analyse. Thus, our study of friction is pure

phenomenological. Here, by friction we refer to dry friction, and not as is, drag.

Friction opposes the relative motion of objects — and this is in fact the most we can say safely, and generally. It is independent of the contact area.

This might feel a little weird, but consider the following argument — say we have an object who has contact area with another object. This contact area is actually a very small fraction of its overall surface area. It is, also, proportional to the pressure.

If we double the surface area of the object, let us assume that the contact area doubles as well. If we keep the normal force constant, the pressure halves. Friction, however, the product of the now half pressure, and the double contact area, remains the same.

This is a very ideal approximation of friction, but we'll leave it here for now.

We differentiate between static friction and kinetic friction. When we apply a force on an object, and yet it does not undergo motion, the static friction assumes a value to balance out the force. This friction is actually related to the normal by $|f_s| \leqslant \mu_s N$. Where μ_s is the coefficient of static friction.

However, it can not keep the object at rest forever, after a certain amount of force is applied, the object undergoes motion and experiences kinetic friction. It is approximately constant and related to the normal by $|f_k| = \mu_k N$, where μ_k is the coefficient of kinetic friction.

Generally, $\mu_k < \mu_s$ and they're both less than 1. Though for some exceptionally rough surfaces, they may have a value greater than 1.

§4.4.3 Spring Force

The relation between the spring force and the displacement of the spring from its equilibrium position x_0 was empirically found by Robert Hooke and is popularly known as Hooke's Law, which states that,

$$F_s = -k(x - x_0) \tag{4.5}$$

where x is the displacement from its equilibrium position, x_0. k is the spring constant and depends on the spring used.

Hooke's law actually fails for rather large displacements but is remarkably good for small displacements. It works not only here, but in a lot more places where the restoring forces are concerned.

The springs can be connected in two main ways, in parallel and in series,

In Parallel

If the springs are in parallel, their constants k_1, k_2 and their displacements x_1, x_2. Then the displacements are equals[1].

1. *Inferred by looking at a simple diagram.*

We can analogously replace these two springs with a single spring of some constant to produce the same effect. This greatly simplifies the phenomenon and is easier to compute.

Thus, let k_{eff} be the effective spring constant, as a way to replace the two springs. Clearly since k_1x_1 and k_2x_2 are two restoring forces on the body, they can be replaced with one equivalent force, $k_{eff}x$. Which gives

$$k_{eff}x = k_1x_1 + k_2x_2 = k_1x + k_2x$$

Thus, springs in parallel can be reduced to a spring of constant k_{eff} where

$$\boxed{k_{eff} = k_1 + k_2},$$

and in general, for parallel springs,

$$\boxed{k_{eff} = \sum k_i.} \tag{4.6}$$

In Series

This is a little more complicated than the prior case. Here, we must note that the forces applied by each spring must be equal, $k_{eff}x = k_1x_1 = k_2x_2$ because the forces on each spring must be 0 .

They're massless which by the second law produce must experience 0 *force.*

Now, we note that the total displacement x is simply $x_1 + x_2$.

We can now solve a series of linear equations,

$$\begin{aligned} k_1x_1k_2 &= k_{eff}xk_2 \\ k_2x_2k_1 &= k_{eff}xk_1 \\ k_1k_2(x_1 + x_2) &= k_{eff}(k_1 + k_2)x \\ k_{eff} &= \frac{k_1k_2}{k_1 + k_2} \end{aligned}$$

This gives us,

$$k_{eff} = \frac{1}{k_1} + \frac{1}{k_2},$$

and in general,

$$\boxed{k_{eff} = \sum \frac{1}{k_i}} \tag{4.7}$$

§4.4.4 Tension

The tension

PART B

Electricity and Magnetism

5 Electrostatics

Motivation: The world around is very well governed largely at day to day scales by electromagnetic interactions. Tensions, friction and a lot more are results of electrical forces between microscopic particles. So a study of electromagnetism is of vital importance to us.

In electrostatics we will deal with the study of stationary charges. We will discuss Coloumb's law and further alternate versions of it for high symmetries like Gauss' law. This forms the basis of all of electromagnetic theory we will encounter.

§5.1 Electric Charge

The theory of electromagnetism is centered around the idea of charge. The fundamental property of charge is their duality — there are two particular types of charges, *positive, and negative.*

The basic *independent* unit of charge is the electron, the charge of which, we denote $-e$ where the negative sign represents that it is negative[1].

1. This is just convention, we could have as well denoted it positive, and it wouldn't have made a difference.

In contrast, the positive charge of equal magnitude is found in proton, whose charge is e. This nice set of duality is rather interesting and maybe linked to a more fundamental concept which we'll see in a moment.

Charges in particular follow two nice set of properties — conservation and quantization.

§5.1.1 Conservation of Charges

Any isolated system of charges, which basically means that no matter is allowed to cross into the boundary of our system; is conserved. What we mean is that the algebraic sum of the charges is always constant.

The isolation isn't exactly the most general criteria, we can let a photon cross over into our system since it carries no charges and observe a very interesting phenomenon, of pair creation.

A photon when exposed to gamma rays may end its existence and create an electron and *positron*, the anti-particle of electron which carries a charge of e but is same in all other respects to an electron[2]. Note that this still ensures conservation, the algebraic sum is still the same. Thus, it follows the "law of charge conservation", which we'll take as something fundamental.

2. In contrast to proton which has a different mass and so on.

Taking this as more fundamental also maybe allows us to answer why the proton has equal magnitude of charge as an electron. Some certain theories suggest that a proton *may* decay into a positron and some uncharged particles.

This event must follow the law of charge conservation and thus implies that a proton has the same charge as that of a positron. However, no one has observed with certainty such a decay.

§5.1.2 Quantization of Charge

Charge in its fundamental form is only present as in an electron or proton, so a system of charges must have a charge of $\pm ne$, where $n \in \mathbb{Z}$. Quarks that exist inside the proton contain a charge in multiplies of $\pm e/3$.

In particular in the neutron two quarks consist of charge $-e/3$ and one with charge $2e/3$, rendering the overall charge neutral. Quarks, however, have yet to be found singularly, thus we have not observed such fractional charges and the basic unit of charges remains e.

§5.2 Coloumb's Law

Coloumb's law, which we take as an empirical law, states that for charges of charge q_1, q_2, the electrical force on the charge 2 by 1 is,

$$\boxed{\mathbf{F}_{21} = k\frac{q_1 q_2}{r_{21}^2}\hat{\mathbf{r}}_{21}} \tag{5.1}$$

where according to standard convention, $\hat{\mathbf{r}}_{21}$ is the unit vector in the direction of the line from charge 1 to 2 and $\mathbf{F}_{21}$ is the force on 2 by 1.
